WARTIME REPORT

ORIGINALLY ISSUED

March 1943 as
Advance Restricted Report

A CORRELATION OF THE DIMENSIONS, PROPORTIONS, AND LOADINGS
OF EXISTING SEAPLANE FLOATS AND FLYING-BOAT HULLS

By Fred W. S. Locke, Jr.
Stevens Institute of Technology

NACA

WASHINGTON

NACA WARTIME REPORTS are reprints of papers originally issued to provide rapid distribution of advance research results to an authorized group requiring them for the war effort. They were previously held under a security status but are now unclassified. Some of these reports were not technically edited. All have been reproduced without change in order to expedite general distribution.

NATIONAL ADVISORY COMMITTEE FOR AERONAUTICS

ADVANCE RESTRICTED REPORT

A CORRELATION OF THE DIMENSIONS, PROPORTIONS, AND LOADINGS
OF EXISTING SEAPLANE FLOATS AND FLYING-BOAT HULLS

By Fred W. S. Locke, Jr.

INTRODUCTION

The design of most machines is a series of compromises, and seaplanes and flying boats are no exception. It is the purpose of this study to determine as far as possible what loadings and proportions have been arrived at by designers, and what, if any, interrelations exist between the loadings and proportions. It is believed that the study may be useful for reference. It should be remembered that differences between the designs considered are in part determined by differing requirements and that the designs are not all of equal merit.

The study has been limited generally to seaplanes built in the last decade, although a few interesting older designs have been included. Only seaplanes built in America, Britain, and Germany have been included. It would have been desirable to include Russian and Japanese planes, but no information was readily obtainable. Correlations are presented between certain of the major items. Additional correlations, involving other items, are no doubt possible.

The source of data is mainly the magazine "Aero Digest," supplemented by other American and British trade journals, as well as certain NACA publications. Information was obtained for 75 flying boats and 23 seaplanes. It was possible, in most instances, to make the data fairly complete by careful analysis.

DATA

The method used consisted of making tables of all the published particulars and specifications, and then with the aid of the three-view drawings (usually published in trade journals with a description of the aircraft) scaling off the

missing items. Certain ones of these items were measured regardless of whether or not a figure for them had been published. This permitted a check on the scaling process.

It was found that areas usually checked to within ± 5 percent and lengths to within ± 2 percent. It was very difficult to get any check on the angles measured off these small drawings, but it is believed that the dead rise is within $\pm 1^\circ$ and the afterbody angle within $\pm 1/2^\circ$. If the drawing was too small, it was enlarged photostatically so that the wing span on the drawing came to about 6 inches.

The longitudinal location of the center of gravity was determined by dropping a perpendicular to the tangent to the forebody keel from the 25 percent mean aerodynamic chord. The vertical location is a pure guess based on the looks of the airplane. The vertical location is not so important, in any case, since the component of force exerting a moment, resistance, is only about one-fifth of the displacement.

Tables I to VI give the tabulated data for all the planes considered.

NOTATION

The following notation and nondimensional coefficients are used:

$$\text{Initial load coefficient, } C_{\Delta_0} = \Delta_0 / wb^3$$

$$\text{Get-away speed coefficient, } C_{V_G} = V_G / \sqrt{gb}$$

$$\text{Brake horsepower coefficient, } C_P = 550 \text{ bhp} / wb^3 \sqrt{gb}$$

$$\text{Forebody length coefficient, } f.b./b$$

$$\text{Afterbody length coefficient, } a.b./b$$

$$\text{Over-all length coefficient, } L/b$$

where

- Δ_0 initial load on the water, pounds
- w specific weight of water, pounds per cubic foot
(usually taken as 64 for sea water)
- b beam at the main step, feet
- V_G got-away speed, feet per second (taken as 10 percent above stalling in the present instance)
- f.b. forebody length defined as the distance from the forward perpendicular to the main step at the kool, feet
- a.b. afterbody length defined as the distance from the main step to the second step or stern post, whichever is shorter, feet
- h height of the main step, porcont beam
- β mean angle of dead rise at the main step, degrees
- α angle between forebody and afterbody koels, dogrees

CORRELATIONS

Boam (fig. 1)

It is generally conceded that the fundamental length characteristic of a seaplane hull is the beam at the main step. Figure 1 shows the boam against the gross weight Δ for flying boats and against $\Delta/2$ for twin-float seaplanes. It is quite similar to a chart prepared by Sottorf (reference 1) although it contains more data.

On this figure contours of the load coefficient C_{Δ} are used as parameters. $C_{\Delta_0} = 0.25$ and $C_{\Delta_0} = 2.00$ are approximately the limits, which means that the limiting beams of float systems that have been built for equal loads are in the ratio of 1:2.

There seems to be a small, though noticeable, trend toward lower values of C_{Δ_0} with increasing gross weight. It may be

that this trend will reverse in the near future when more powerful engines become available.

It will also be noted that float seaplanes have somewhat higher values of C_{Δ_0} than flying boats, although actually the two groups overlap very considerably.

Get-away Speed (fig. 2)

Dichl (reference 2) showed that there was a connection between the static load coefficient and the get-away speed coefficient of the form:

$$\frac{C_v}{G} = 7.4 C \frac{\frac{1}{3}}{\Delta_0} \quad (1)$$

A logarithmic chart was prepared of the present information and is shown in figure 2. The mean line is given by:

$$\frac{C_v}{G} = 8.7 C \frac{\frac{1}{3}}{\Delta_0} \quad (2)$$

It should be pointed out that for the present study, the get-away speed was taken as 10 percent above the stalling speed, and that the stalling speeds were calculated for all airplanos included in this study, since the published figures are almost invariably optimistic. Adding 10 percent to Dichl's constant gives 8.1, which is not so far from the present, and probably more modern, information. It is not known how Dichl defined get-away.

Forobody Length (fig. 3)

The forobody length can be related to the static load coefficient as shown in figure 3. The equation of the mean line is:

$$\frac{f.b.}{b} = 3.5 C_{\Delta_0}^{\frac{1}{3}} \quad (3)$$

The primary purpose of having considerable length to the forebody is to provide flotation at rest and to prevent nosing under when taking off or alighting. It does not seem likely that the length of the forebody can have much effect at planning speeds, except insofar as the length affects the shape in the region of the step.

Taking the limits of the cluster of points, it is found that forebody lengths in the ratio of 1:1.6 have been used for the same load and beam. This is quite a wide variation. It is not known whether the length given by equation (3) is the best one - it is merely a mean.

Aftorbody Length (fig. 4)

There seems to be slightly more confusion regarding the proper length of the aftorbody. Hydrodynamically, the aftorbody serves two functions - to assist getting over the hump and to provide flotation at rest. At high speed its effect is quite often detrimental. The requirements are, therefore, conflicting - a long aftorbody at low speeds and a short one at high speeds. The average of contemporary opinion is that:

$$\frac{a.b.}{b} = 2.5 C_{\Delta_0}^{\frac{1}{3}} \quad (4)$$

The data obtained is shown in logarithmic form in figure 4. The limits indicate that for equal load and beam, aftorbody lengths in the ratio 1:1.9 have been built.

Hull Length (fig. 5)

Equations (3) and (4) may be added together to give:

$$\frac{L}{B} = 6.0 C_{\Delta_0} \quad (5)$$

The actual data are shown in figure 5, which is similar in nature to one prepared by Richardson (reference 3). The mean line (fig. 5) actually makes the constant 6.05 in equation (5).

This is a rather minor point; a more important one, however, is that for a given beam and load the maximum variation of the hull length is in the ratio of 1:1.3. This indicates that there was reasonable certainty in the minds of the designers as to what length to make the hull; but much less as to where to locate the step.

Center of Gravity (fig. 6)

Figure 6 shows the location of the center of gravity non-dimensionally. At first glance it would appear that here is a major difference between float seaplanes and flying boats. However, it must be remembered that the vertical location of the center of gravity is about one-fifth as important as the longitudinal.

Actually the most important thing brought out by this figure is that the center of gravity averages about 0.4 of the beam forward of the step. It is believed that the best location for proper hump and planing characteristics will depend on the forebody shape and should be determined by model test in early stages of a design.

Brake Horsepower Necessary (fig. 7)

Having proportioned the hull it is very desirable to know whether sufficient power is available to lift the airplane off the water. A brake horsepower coefficient has been plotted against the product of C_{Δ_0} and C_{V_G} (fig. 7). After the

plot had been prepared, a line was drawn to show the minimum brake horsepower available. As an afterthought, for those hulls with published take-off time, the load for infinite take-off time was computed by Diehl's method (reference 4); and then C_{Δ_0} and C_{V_G} were recomputed.

Plotting the new product of C_{Δ_0} and C_{V_G} against the old value of C_P , gave the startling result that none of these points fell above the line previously drawn. It appears, therefore, that the brake horsepower available should be greater than the relation:

$$C_P = 0.273 C_{\Delta_0} \times C_{V_G} \quad (6)$$

The brake-horsepower coefficient was defined as:

$$C_P = \frac{550 \text{ bhp}}{\frac{w}{b} \sqrt{g b}}$$

This coefficient is dimensionally in accordance with the other NACA nondimensional seaplane coefficients. It contains no propeller efficiency nor the rate at which thrust changes with speed. As long as the limitations are recognized, it is simple and ought to be useful. Since it is most likely to be used for the full-size seaplane which operates in sea water, the coefficient may be reduced to:

$$C_P = \frac{1.52 \text{ bhp}}{\frac{w}{b}}$$

This is a sort of power-available coefficient. The product of C_{Δ_0} and C_{V_G} might be considered a power-required coefficient.

Experimental Towing Tank,
Stevens Institute of Technology,
Hoboken, N. J.
